Abstract. Using the JET A2 ICRF antennas \textsuperscript{[1]}, experiments were carried out to assess the performance of three different dipole phasing configurations relevant for the operation of the ICRF antenna in ITER. Three similar discharges with dipole (0\pi0\pi), “symmetric dipole” (0\pi0\pi) and “super dipole” (00\pi\pi) phasings were compared. In the “super dipole” case, higher coupling was confirmed but lower heating efficiency and much stronger plasma wall interaction were observed, as corroborated, respectively, by the analysis of the diamagnetic energy response to the ICRF power steps and by the observation of a considerable temperature rise of the antenna limiters and septa in the 00\pi\pi case. These observations were found to be in line with simulations of the ICRF wave absorption and with High Frequency Structure Simulator (HFSS) modelling of the RF fields near the antenna \textsuperscript{[2]}.

INTRODUCTION

The main difficulty of Ion Cyclotron Radio Frequency (ICRF) heating schemes in large tokamaks comes from the fact that the fast waves launched by the antenna have to cross a region of low density – where the waves are typically evanescent – before reaching the main plasma. The wider this region the lower the antenna coupling and consequently less power can be effectively coupled to the plasma for a given voltage applied to the antenna. The amount of RF power that can tunnel through the evanesence region depends on the decay length of the wave excited. For a given RF frequency, waves with smaller parallel wave components $k_\parallel$ are less evanescent than waves with larger $k_\parallel$ and therefore different antenna phasings (leading to different $k_\parallel$ spectra excited) are expected to show different coupling properties. On the other hand, the wave absorptivity increases with $k_\parallel$ and thus the overall performance of an ICRF system depends on a compromise of producing an antenna excitation with low enough $k_\parallel$ to ensure an acceptable plasma coupling but with high enough $k_\parallel$ to still feature satisfactory ICRF absorption \textsuperscript{[3]}. The influence of ICRF antenna phasing in the JET tokamak was already studied in the past \textsuperscript{[4-6]}. During the last experimental campaign at JET, the performance of three dipole phasings of the A2 antennas was readdressed. The main results of these experiments are reported below.

EXPERIMENTAL OBSERVATIONS

The experiments were performed in L-mode with a magnetic field of $B_0=3T$, a plasma current of $I_p=2MA$, a central density of $N_e=3.5\times10^{19} \text{ m}^{-3}$ and an antenna-separatrix distance of $11.0\pm0.5\text{cm}$. Minority hydrogen ICRF heating at $f=42\text{MHz}$ was used with $\sim7\%$ of H and about 4MW ICRF power was applied. In Fig.1 various quantities of three similar discharges with $0\pi0\pi$, $0\pi\pi0$ and $00\pi\pi$ antenna phasings are compared.

First note that despite the fact that the loading (g) is higher for the $00\pi\pi$ pulse, the other two discharges exhibit much higher heating efficiency, as clearly seen on the larger values of electron temperature (c), diamagnetic energy (d) and neutron rate (e) reached after the RF power is applied. The heating efficiencies inferred from break-in-slope analysis of the plasma diamagnetic energy response are $\eta=0.85\pm0.1$, $\eta=0.84\pm0.1$ and $\eta=0.54\pm0.1$ for the pulses with $0\pi0\pi$, $0\pi\pi0$ and $00\pi\pi$ phasings, respectively. Also note that, in spite of the somewhat lower bulk plasma density, the radiation losses in pulse 74091 are larger, indicating a higher level of impurities in the plasma. This observation is also supported by spectroscopic measurements at the plasma edge.
Another striking difference between the 00ππ discharge and the other two pulses is depicted in Fig.1h, where the time traces of the temperature measured by an infra-red (IR) camera [7] on the equatorial region of the central septum of antenna B are compared. The surface temperature for the pulse with 00ππ phasing rises above 800°C while the temperature during the two other discharges lies around 400°C. As a matter of fact, the antenna septa and close limiters reach the highest surface temperatures in pulse 74091 and a ‘bright spot’ was observed in the visible camera close to antenna B, although the plasma equilibrium and the ICRF power was similar for the 3 discharges.

This stronger plasma-wall interaction observed in pulse 74091 is related to enhanced excitation of coaxial modes and to larger RF sheath rectification, i.e. to the fact that the net parallel RF electric field excited close to the antenna is larger for the 00ππ phasing configuration than for the other two cases and non-resonant acceleration of charged particles in the edge / SOL is enhanced. Numerical modelling of the A2 antennas using HFSS confirms that the near fields and the image currents excited in the antenna box are indeed larger in the super-dipole case, as discussed in detail in [2].

MODELLING

The ICRF power spectra excited by the A2 antennas computed with the ANTITER code [8] using the main parameters of the experiments are shown in Fig.2a for the 3 different dipole phasings discussed: 0π0π (solid), 00π0 (dashed) and 00ππ (dash-dotted). The spectra were normalized to produce the same total power for all cases.

Note that in the standard dipole configuration (0π0π) roughly 80% of the power is launched around |k_//| ≈ 6.5m⁻¹ whereas the super-dipole phasing (00ππ) has ~90% of the power associated to lower |k_//| ≈ 2.5m⁻¹ values and hence features higher coupling (Fig.1g). The single-pass absorption efficiency computed with the 1D ICRF TOMCAT code [9] for the experimental conditions of the studied pulses is plotted in Fig.2b as function of the k_// wave-numbers considered. In these simulations, the fast wave is launched from a propagative region inside the plasma and thus coupling properties and edge / SOL losses are not described. Moreover, being a 1D (radial) code, TOMCAT does not include the excitation of coaxial modes in the torus nor the asymmetry in the k_// spectrum absorption caused by poloidal field effects. Despite the simplicity of the model, these results already shed some light on the different heating performances seen experimentally: In the 0π0π and 00π0 discharges, a fair fraction of the power is launched in a k_// range where the wave absorption is efficient while the 00ππ phasing launches the ICRF power in a k_// range where the absorptivity is small (due to the narrower ICRF absorption region of the low k_// waves). The heating efficiencies estimated by convoluting the absorptivity given by TOMCAT with the antenna spectra shown in Fig.2a are indicated in the legend of Fig.2b. The values for the 0π0π and 00π0 phasings are in fair agreement with the experimental results while the heating efficiency for the 00ππ case is somewhat underestimated. This comes from the fact that in this simplified model it is considered that the power that is not absorbed in a single-pass is lost, which is probably a too strong assumption for the low absorptivity cases. 3D full-wave modelling that describes the antenna coupling as well as the excitation of coaxial modes including parasitic edge losses is ongoing.
Three similar JET discharges with different ICRF dipole antenna phasings were described. As expected, the “super-dipole” 00ππ phasing, which privileges the excitation of waves with low k// values, features higher plasma coupling than the other two studied phasings (0π0π and 0ππ0). For this phasing configuration, however, it was observed that the heating efficiency was significantly lower and that the plasma-wall interactions were strongly enhanced. The latter is mainly attributed to enhanced excitation of coaxial modes and particularly to higher net parallel electric fields due to RF sheath rectification close to the antennae, which enhance parasitic RF dissipation in the scrape-off layer. 1D modelling of the ICRF wave absorption including the toroidal antenna spectra excited in each phasing configuration corroborates the different heating efficiencies observed experimentally.

ACKNOWLEDGEMENTS

The authors would like to thank R. Koch and P. Lamalle for their contribution to this work. This work was carried out within the framework of the European Fusion Development Agreement. The views and opinions expressed herein do not necessarily reflect those of the European Commission.
